I. INTRODUCTION

Invisibility, mimicry, and cloaking are perpetual problems in both wildlife and inorganic nature. A new fresh impetus to the progress in this field has been given by the concept of metamaterials [1], allowing us to design a cloaking structure that surrounds an object making it invisible to an outside observer. Different approaches to achieve invisibility cloaking have been proposed including multilayered shells that may make even plasmonic particles invisible [2], being also tuned by graphene [3] or nonlinear layers imbedded into multishell structures [4], or magneto-optical shell activated by an external magnetic field [5,6]. It was recognized that the invisibility cloaking becomes possible as a product of the powerful concepts of the so-called transformation optics [7–10], and it was studied for a variety of applications including radar detection, sensors, and detectors [11–13]. Unfortunately, most of the suggested methods for invisibility cloaking require the creation of specially designed shells or media with perfect parameters making difficult a practical realization of many invisibility concepts [1,14]. Recently we suggested an approach for the realization of tunable invisibility cloaking and a direct switching from visibility to invisibility regimes and back [15]. This approach is based on two basic ideas.

The first idea is to archive the scattering cancellation by employing the properties of the Fano resonance [16,17]. We can realize the Fano-type interference if a spectrally narrow band (of any origin) interacts with a broad spectrum representing an effective background. Because the phase of a resonant mode changes by π across the narrow band, its amplitude interferes constructively with the background producing a sharp peak in the intensity spectrum at a certain frequency, and also destructively at the other frequency exhibiting a vanishing intensity. The resulting asymmetric line shape is attributed to the Fano resonance.

It is well known that the Fano resonance has been observed across many different branches of physics [18–21] including plasmonic [22–24] and dielectric structures [25–29]. If there are no parts of background avoiding the above interaction, the Fano relation takes the form [15]

\[ I(\omega) = \frac{(q + \Omega)^2}{1 + \Omega^2} \sin^2[\Delta(\omega)], \tag{1} \]

where \( q = \cot \Delta \) is the Fano asymmetry parameter, \( \Omega = (\omega - \omega_0)/(\Gamma/2) \), where \( \omega_0 \) and \( \Gamma \) correspond to the position and the width of the narrow band, and \( \Delta(\omega) = \varphi_A(\omega) - \varphi_B(\omega) \) is the phase difference between the narrow resonant and continuum states correspondingly. The main point of the approach is based on the characteristic line shape of the Fano intensity that vanishes at a specific frequency \( \omega_{zero} = \omega_0 - q\Gamma/2 \). It means that the scattering by an object completely vanishes. Note that \( \omega_{zero} = \omega_0 \) at \( q = 0 \), \( \omega_{zero} < \omega_0 \) at \( q > 0 \), and \( \omega_{zero} > \omega_0 \) at \( q < 0 \).

The second idea is to employ the well-known Mie resonances. The case of an infinite cylinder, referred to as the Lorenz-Mie theory, corresponds to a two-dimensional (2D) problem of scattering in the plane normal to the symmetry axis \( z \), and it involves cylindrical functions in the infinite series of the analytical Mie solution [30]. As a result of the interference of the nonresonant and resonant scattering, the spectra of the squared Lorenz-Mie scattering coefficients \( |a_n|^2 \) demonstrate asymmetric profiles with either sharp increase or drop at the resonance frequencies of the cylinder eigenmodes. The scattering coefficients \( |a_n|^2 \) can be presented in the form of infinite cascades of resonances each of which is described by the conventional Fano formula (1) as was shown numerically [15,30] and then analytically for the cases of infinite cylinder [31] and sphere [32].

Employing these two basic ideas, one can demonstrate that the resonant Mie scattering from an infinite dielectric cylinder vanishes at frequencies of \( \omega_{zero} \) and the cylinder...
becomes invisible at any angle of observation. Importantly, for a high-index dielectric cylinder a typical asymmetric Fano profile has a local maximum and minimum located close to each other. Such a proximity allows us to realize *switchable invisibility* of a macroscopic object transforming from the visible to invisible regimes and back, without using any coating layers. The idea was confirmed experimentally at microwaves by employing high temperature-dependent dielectric permittivity of heated water in a plastic tube [15]. In contrast to this earlier study on the scattering and invisibility phenomena of a macroscopic object transforming from the visible to invisible regimes and back, the scattering intensity we choose standard scattering efficiency $Q^R/Q_{PEC}$.

Next we continue with numerical calculations of the scattering from a finite dielectric cylinder $Q^{L/L}$, namely, a finite-extent dielectric resonator with the radius $r$ and length $L$. The resonator with the dielectric permittivity $\varepsilon_1$ is embedded in the transparent and homogeneous surrounding medium with the dielectric permittivity of $\varepsilon_2 = 1$. The spectra were calculated by using the CST Microwave Studio software. We calculated the scattering efficiency $Q^{L/L}$ as the radar cross section of the cylindrical resonator divided by the projected cross section of the resonator $S = 2\pi L$. Figures 2(b)–2(f) show the total Mie scattering efficiency from finite cylindrical resonator $Q^{L/L}$ for different aspect ratios $r/L$ together with the scattering spectra of infinite perfect conducting metal cavities $Q_{PEC}$. Using the standard nomenclature [33], the resonator modes are identified to be TM$_{nkp}$ and TE$_{nkp}$ where $n$ is an integer related to the rotational behavior of the mode, $k \geq 1$ identifies resonance number for the modes with fixed symmetry $n$, and $p$ enumerates the mode relative to the cylinder axis direction. For a rather long cylindrical resonator ($L > r$), the low-frequency spectrum $Q^{L/L}$ demonstrates several strong additional "resonator modes" in comparison with the spectrum of the infinite cylinder $Q^R$ (Fig. 2). Resonator modes have an obvious origin being related directly to the appearance of the end faces of a finite cylinder.

New (Fabry-Perot or resonator) modes introduce additional scattering that suppress partly or completely spectral windows of the invisibility, specially for the lowest Fano window corresponding to the TE$_{11}$ Mie resonance. With increasing of $r/L$, all resonances that have a genetic link with the Mie modes of the infinite cylinder demonstrate only a slight high-frequency shift. Alternatively, exactly what one might expect, the resonator modes demonstrate a strong shift from the low to higher frequencies with decreasing of the normalized length $L/r$, as clearly illustrated by the behavior of the TM$_{11}$ resonator mode in Fig. 2.

As a result, for a resonator with parameters $r/L \geq 1$ the lowest TE$_{11}$ window of invisibility at $\chi \approx 0.6$ completely recovers [marked by red circles in Figs. 2(a) and 2(f)].

**III. EXPERIMENTAL APPROACH**

To demonstrate experimentally the realization of the invisibility of the cylindrical resonator with high refractive index without any coating layers, we use a plastic cylinder filled with water that is characterized by dielectric permittivity of $\varepsilon \approx 80$ at room temperature and $\varepsilon \approx 50$ at 90 °C in the microwave frequency range [34]. The microwave scattering spectra $Q^{L/L}$ of the cylindrical resonator depending on the $r/L$ parameter and water temperature were measured in an anechoic chamber. A rectangular horn antenna (TRIM 0.75 to 18 GHz; DR) connected to a transmitting port of a vector network analyzer Agilent E8362C is used to approximate a plane-wave excitation. The cylindrical rod of water with radius $r = 20$ mm and variable height is placed into the far-field region of the horn antenna at a distance of 2.5 m. The similar horn antenna is employed as a receiver and placed 2.5 m distance from the cylindrical rod. For the TE polarization, the electromagnetic wave incident perpendicular to the resonator.
FIG. 2. Spectral dependencies of the total scattering efficiency of the infinite homogeneous dielectric cylinder \( Q^0 \) (a) and finite cylindrical resonator \( Q_{\text{PEC}}^{L} \) for different ratio \( r/L \) (b)–(f), solid curves. Spectral dependencies of the infinite \( Q_{\text{PEC}}^\infty \) (a) and finite \( Q_{\text{PEC}}^{L} \) (b)–(f) perfect conducting metal cavities, dashed curves. TE polarization, \( \varepsilon_1 = 60, \varepsilon_2 = 1 \). The size parameter \( \chi = r\omega/c = 2\pi r/\lambda \).

We observe experimentally a strong suppression of scattering at frequencies corresponding to the Fano dips in the function \( Q^{L} \). Figure 3 shows an invisibility effect, namely suppression of scattering lower than PEC level \( Q_{\text{PEC}}^{L} \) due to the TE\(_{11}\)–Fano resonance at \( \chi \approx 0.5 \) for \( r/L = 0 \) (\( r/L = 0.03 \) in experiment) [Fig. 3(a)], at \( \chi \approx 0.55 \) for \( r/L = 0.6 \) [Fig. 3(b)], and at \( \chi \approx 0.6 \) for \( r/L = 1 \) [Fig. 3(c)]. Therefore the incident TE-polarized electromagnetic wave passes the cylindrical resonator without scattering making it invisible from any angle of observation. For \( r/L = 0.6 \), the TM\(_{11}\) resonator mode at \( \chi \approx 0.58 \) partly suppress spectral windows of invisibility. Nevertheless, with future decreasing of \( r/L \), the TM\(_{11}\) resonator mode shifts to higher frequencies and the lowest TE\(_{11}\) Fano window of invisibility completely recovers.

To demonstrate dramatic difference in the scattering between the maximum and minimum of the Fano Mie line shape, we calculated numerically a structure of the magnetic field around and inside the cylindrical resonator depending on \( r/L \). Figure 4 shows that for the TE\(_{11}\) Mie resonance in the regime of Fano invisibility we observe practically complete suppression of the scattering, see Figs. 4(b), 4(d), and 4(f). For those normalized frequencies the resonant field near the cylinder’s boundary inside the rod mimics the incident field distribution, Figs. 4(h), 4(j), and 4(l). As a result, an incident TE-polarized electromagnetic wave passes the cylindrical resonator without scattering, that is, the resonator becomes invisible from any angle of observation without additional coating layers. At the same time inside the resonator one can observe very strong Mie resonance which nevertheless do not disturb the incidence wave because of the Fano condition.
IV. INVISIBILITY MAP

The calculations show that by adjusting the frequency and dielectric permittivity, a homogeneous high-index cylindrical resonator can be made essentially invisible without any additional cloaking layers.

To analyze the invisibility dynamics, we calculated the difference $Q_{r/L} - Q_{r/L}^{\text{PEC}}$ as a function of the resonator dielectric permittivity $\varepsilon_1$. We found that the scattering efficiencies of dielectric cylindrical resonator and PEC coincide when $\varepsilon_1$ is about 10. At $\varepsilon_1 > 10$ the invisibility dynamics appears for the TE110 Mie resonance. The invisibility map demonstrated in Fig. 5 shows the regions of invisibility $[Q_{r/L} < Q_{r/L}^{\text{PEC}}]$ with respect to the controllable parameters $\chi$ and $r/L$ for $\varepsilon_1 = 60$. The regions of the invisibility are shaded in white. From Fig. 5 it is clearly seen that the invisibility in low-frequency spectral regions follow strong Fano resonance for TE110 Mie mode.

As can be seen from Figs. 2 and 5, for a rather long cylindrical resonator ($L > r$), the resonator mode TM11 introduces additional scattering within TE110 window of invisibility. The effect regains with increasing $r/L$ when the resonator modes demonstrate a strong shift from the low to higher frequencies. For structural parameters $r/L \gtrsim 1$ the lowest window of invisibility completely recovers.

All resonant modes manifest themselves as asymmetric shapes with no sharp difference between them, e.g., as for the case of TE010 and TE110 modes. However, we do not describe invisibility with the lower-frequency TE010 mode.

FIG. 5. Invisibility map for a homogeneous dielectric resonator in the low-frequency spectral region. Shaded areas define the regions of strong scattering. Open domains map the region of suppressed scattering $Q_{r/L}$ in comparison with the PEC scattering $Q_{r/L}^{\text{PEC}}$. TE polarization, $\varepsilon_1 = 60$, $\varepsilon_2 = 1$.

FIG. 4. Numerical results. Magnetic field map for the $H_z$ component around cylinders (a)–(f) and inside cylinders (g)–(l). Shown are strong Mie scattering (a) and (g) for $r/L = 0$, $\chi = 0.48$, (c) and (i) for $r/L = 0.6$, $\chi = 0.52$, (e) and (k) for $r/L = 1$, $\chi = 0.57$, and the Fano invisibility regime (b) and (h) for $r/L = 0$, $\chi = 0.50$, (d) and (j) for $r/L = 0.6$, $\chi = 0.54$, (f) and (l) for $r/L = 1$, $\chi = 0.59$. TE polarization, $\varepsilon_1 = 60$, $\varepsilon_2 = 1$. 

FIG. 3. Low-frequency region of the calculated scattering efficiency $Q_{r/L}$ (black short-dashed curve), scattering efficiency of the perfect metallic conductor PEC $Q_{r/L}^{\text{PEC}}$ (green long-dashed curve), and the experimentally measured scattering efficiency of a cylindrical tube filled with water (red curve): (a) $r/L = 0$, (b) $r/L = 0.6$, and (c) $r/L = 1$. TE polarization, $\varepsilon_1 = 60$, $\varepsilon_2 = 1$. 

Zoom x10

(a) (b) (c) (d) (e) (f)

(g) (h) (i) (j) (k) (l)
The reason is that the Fano parameter $q$ has positive values for the TE_010 mode at low frequencies [30], whereas $q < 0$ is only for higher-order modes. As a result, the TE_010 resonant mode generates the scattering cancellation in the lower frequency range $\chi < 0.33$ [see Fig. 2(f)] and invisibility due to the TE_010 mode is much weaker respective to the TE_110-mode invisibility. Another issue is why the “dark” TE_210 mode does not demonstrate the scattering cancellation. The modes with different $n$ (the first index of TE_{nkp}) do not interfere, hence the TE_210 mode cannot cancel the intensive background scattering related to the TE_110 mode and other modes with $n \neq 2$.

V. DEMONSTRATION OF SWITCHABLE INVISIBILITY

Figure 2 shows that for the high-index dielectric resonator an asymmetric Fano profile has a maximum and a minimum located close to each other. This proximity can be used for the demonstration of the switching between visibility and invisibility. To prove the concept of Fano invisibility experimentally, we take advantage of the strong temperature dependence of the water permittivity $\varepsilon_1$ in the microwave frequency range [34]. It changes from $\varepsilon_1 = 80$ at $20^\circ$C to $\varepsilon_1 = 50$ at $90^\circ$C. Such unique dependence of $\varepsilon_1$ leads to a considerable temperature shift of the maxima (strong scattering) and minima (possible invisible regime) of the Fano-Mie resonance modes, as seen in Fig. 6 for TE_010 and TE_110 bands. When a high-frequency wing of TE_110 Fano line shape moves through a fixed frequency we observe a strong change of the scattering intensity from high to very small values. Therefore, the Fano resonance makes it possible to switch the scattering of a cylindrical resonator filled with water from the visible regime of strong Mie scattering ($\varepsilon_1 = 64$, water at $T = 80^\circ$C) to the invisible regime ($\varepsilon_1 = 72$, water at $T = 35^\circ$C) at the same frequency of 1.22 GHz.

VI. CONCLUDING REMARKS

We have demonstrated that different Mie resonances of a homogeneous dielectric resonator with high refractive index are responsible for sharp Fano resonances in the TE-polarized scattered spectra. The unique property of the characteristic Fano line shape is that the transmission intensity vanishes at a special frequency. This means that the scattering completely vanishes at this frequency, and an object becomes invisible at any angle of observation. The effect of the Fano invisibility has been suggested earlier for an infinite dielectric cylinder in a low-frequency spectral region [15]. Here we have studied the scattering from a finite-length dielectric resonator and revealed that the spectra of a rather long resonator ($L > r$) contain additional TM_{nkp} and TE_{nkp} (p \neq 0) modes that superimpose in the low-frequency region and introduce additional scattering suppressing or completely removing the spectral windows of the invisibility. However, when the ratio $r/L$ becomes larger, the resonator modes shift to higher frequencies and the invisibility window completely recover at $r/L \geq 1$. As a result, a finite-length dielectric resonator becomes invisible from any angle of observation at certain frequencies for the TE-polarized waves. We have verified these theoretical predictions in microwave experiments.
